The emergency department approach to violently injured patient care: a regional survey

D L Wilkinson, E M Kurtz, P Lane,* J A Fein

Objective: Since the early 1990s public health workers have challenged healthcare practitioners to take an active role in violence prevention with patients aged 10–24 years. Emergency department (ED) clinicians are uniquely positioned to identify, assess, and refer youth involved in violent events. The objective of this study was to describe ED directors’ estimate of the number of violently injured youth seen, the presence of established protocols or guidelines for handling youth violence, and the type of training programs offered to ED physicians regarding this issue.

Methods: The authors conducted a survey of EDs (n = 64) in the Philadelphia metropolitan region to determine the standard of ED care for violently injured youths. Half of the EDs were in urban areas and half in suburban.

Results: A total of 41 out of 64 (64.1%) ED directors completed and returned the written questionnaire. In addition to treating the specific injuries sustained, ED responses to youth violence primarily involved talking with patients about the events surrounding the injury. The estimated number of violently injured youth seen per month varied considerably. Twenty four directors (58.5%) estimated that their institution treated fewer than 10 per month; 10 (24.4%) reported 11–30, and seven (17.1%) mostly large urban hospitals, saw more than 30 per month. Although most hospitals reported that the staff counsels patients about safety concerns, only 17% offered their staff formal training programs on youth violence.

Conclusions: To address the prevention of youth violence, EDs need specific training programs for ED staff, as well as systematic risk assessment and referral resources for structured intervention and follow up.

P
rompted by alarming rises in youth violence rates in the United States, medical professionals have been viewing youth violence as a public health issue since the early 1990s. Prothrow-Stith suggested that emergency department (ED) workers should conduct risk assessments, counseling, and referrals to community support services for these youth. In 1996 a panel of the American Academy of Pediatrics developed a model protocol for dealing with adolescent assault victims. The panel recommended that ED practitioners develop treatment plans to reduce the likelihood of re-injury and to deal with stress reactions. Similarly, in 1999, the American Academy of Pediatrics Task Force on Violence called for “preventive education, screening for risk, and linkages to necessary intervention and follow-up services”. Other public health and medical experts have published similar calls to action.

Health based violence prevention programs are often based in schools or in the primary care office. Urban adolescents, who are at highest risk for severe violent injury, often seek acute medical care in the ED rather than at primary care sites. There is some evidence that hospital based violence prevention programs can be implemented to influence future risk factors for re-injury. Although ED based interventions have not demonstrated equal efficacy, studies indicate that clinicians are able to assess important psychosocial needs and link injured youth with social service agencies. However, it is not clear if ED personnel have begun to incorporate violence prevention efforts into their routine practice. The objective of this study was to describe ED directors’ estimate of the number of violently injured youth seen, the presence of established protocols or guidelines for handling youth violence, and the type of training programs offered to ED physicians regarding this issue.

METHODS

The present study examines ED based approaches to patients injured as a result of community youth violence, excluding child abuse. A written, self-administered questionnaire was

Abbreviations: ED, emergency department.
sent to the directors of 64 EDs in the Philadelphia metropolitan area, one half (32) of which were urban and the other half suburban. Research assistants made up to three telephone calls to obtain responses. The questionnaire was adapted from a previously used measure, and included 10 forced choice and open ended questions. (see appendix A) We used SPSS (version 11.0, SPSS Inc, Chicago, IL, USA) for the data analysis. This study was approved by the University’s institutional review board.

RESULTS
A total of 41 out of 64 (64.1%) complete questionnaires were returned—81.3% for urban programs and 46.9% for suburban programs. The estimated number of violently injured youth seen per month varied considerably. Twenty four directors (58.5%) estimated that their institution treated fewer than 10 per month; 10 (24.4%) reported 11–30, and seven (17.1%) mostly large urban hospitals, saw more than 30 per month. (table 1)

Identification and event details
Almost all reported that ED personnel routinely determine the context of the event that caused the injury, and more than three quarters report that the staff regularly asked who caused the patient’s injury (table 2).

Assessment for safety and risk
Most ED directors also reported that their staff members assess the risk for further injury (table 2). Most stated that clinicians talk with the patient about safety concerns while in the ED; just over one quarter reported that ED personnel determine the likelihood of a repeat attack, and one fifth reported that they determine whether or not the patient had plans to retaliate.

Intervention and referral
Most directors acknowledged that their staff members do not routinely intervene on behalf of a violently injured patient. About one third routinely referred injured patients to either a social worker or chaplain or counselled the patient themselves about possible ways to increase their safety. One quarter routinely provided information about community based violence prevention programs. Mandatory reporting of penetrating wounds is required in Philadelphia but there is no systematic monitoring of compliance with this requirement. Only two hospitals routinely contacted the police or suggested that the victim do so.

We asked ED directors to specify which health professionals should ask patients about the events that led to their violent injuries (table 3); most felt that physicians or nurses should ask about the event. However, slightly more than half felt that this was an appropriate task for physician’s assistants, nurse practitioners, and/or social workers. Only 20% thought chaplains or psychologists would be appropriate. Only seven (17.1%) respondents stated that their ED had a formal violence prevention program. Most of the others stated that their hospital had never considered having such a program although many indicated that they would be interested in collaborating with existing programs.

DISCUSSION
The ED is often the only source of health care for youth most likely to sustain intentional injuries. Psychosocial assessment of violently injured youth has been endorsed by several professional organizations. The incidence of intentionally inflicted (non-child abuse) injuries cared for in the EDs studied varied considerably. This is not surprising given the geographic concentration of violence perpetration in urban Philadelphia.

In general, ED directors do not believe it is likely that patients are referred to specialized hospital staff or programs to prevent further violent injury. The lack of existing violence prevention and staff training programs is especially vexing for hospitals with more than 20 incidents per month because, although they may benefit the most from such a program, they may also be the busier EDs and therefore have less time to devote to such an endeavor.

Similar results have been reported by Fein and colleagues. Our study did not find the high rate of referrals to social workers or clergy reported in the Fein study. This may reflect...
Key points

- Emergency department (ED) directors recognize the need for ED clinicians to perform some psychosocial assessment of young violently injured patients.
- Although most ED practitioners will address a violently injured patient’s overt safety concerns, few ask directly about retaliation or the likelihood of repeat attack.
- When faced with social or safety concerns, ED practitioners are more likely to address them directly than to access resources outside of the immediate medical surroundings.
- Formalized youth violence prevention and training programs for ED staff are rare.
- Additional research on ED based youth violence programs is needed.

the fact that most of the clinicians surveyed in the earlier study worked in a tertiary care children’s hospital where there was full time social work coverage.

Limitations

The data collected were from the fifth largest city in the United States and one that has a relatively high violent crime rate.56 Neither the validity nor reliability of the survey instrument was tested, although many of the questions were used in an earlier study.14 Because the majority of the 23 non-responders were suburban hospitals, the data are likely to underrepresent hospitals with lower volumes of intentional youth violence. It is possible that non-responding suburban ED directors did not consider this issue important enough to warrant a response.

We excluded child abuse and domestic violence from this study because many of the issues related to the care of these patients are distinct from those of youth violence. Finally, our data are based on the perceptions of ED directors and we do not know how accurately these perceptions reflect actual practices. Fein’s study demonstrated that clinicians have misconceptions about youth violence protocols within their home institution, with 85% of respondents believing that the hospital had a formal protocol when in fact they did not.19

This study demonstrates that ED directors support the promotion of clinician education around the management of violently injured youth, and most expressed an interest in collaborating with violence prevention programs at other institutions. However, it is important to recognize that the behaviors of ED clinicians may not change unless ED based violence prevention programs demonstrate some benefit to their patients and to society. An evaluation of the ED based Boston Violence Prevention Project, which provided initial ED assessment and subsequent community based follow up, found no detectable differences between the treatment and control groups.14 There is a clear need for empirical evidence of the efficacy of ED based safety screening and psychosocial assessment of the violently injured youth.
