Smoke alarms, fire deaths, and randomised controlled trials

Each year about 300 000 people die in fires. Most of these deaths occur in the home and children and the elderly are at greatest risk. The absence of a smoke alarm is a strong risk factor for death in the event of a house fire. In some countries, there has been a substantial increase in the proportion of households with smoke alarms over the past two decades. In England and Wales, the proportion of homes with alarms increased from 0% in 1985 to 75% in 1995. This increase in alarms coincided with a substantial fall in fire deaths, although a number of factors apart from smoke alarms might have been responsible for the decline. Despite the overall increase in smoke alarm use, ownership is substantially lower (less than 50%) in disadvantaged inner city neighbourhoods and among families living in rented accommodation. Because the risk of fire and fire related injury is greater in rented and inner city accommodation, increasing the prevalence of functioning smoke alarms in these homes may have a disproportionate effect on the occurrence of fire deaths and injuries. This would also have the potential to reduce socioeconomic differentials in mortality. The social class gradient for deaths due to residential fires is steeper than for any other cause of death in childhood. The death rate from fire and flames for children in social class V is 16 times that of children in social class I. A non-randomised controlled trial reported a substantial reduction in fire related injuries associated with a programme to giveaway smoke alarms in a materially deprived area of Oklahoma City.

Two papers in this journal have addressed the problem of increasing smoke alarm use. DeGuiseppi et al reported a smoke alarm giveaway programme conducted in two deprived inner London boroughs. Over 20 000 smoke alarms were distributed door to door in randomly selected wards by a coalition of statutory and voluntary agencies. The effectiveness and cost effectiveness of the programme in preventing fires and fire related injury is being evaluated in a randomised controlled trial. A paper in this issue by the ISCAIP Smoke Detector Legislation Collaborators addresses a second strategy for increasing smoke alarm installation, summarising smoke alarm laws internationally (p 254). Many countries have enacted comprehensive smoke alarm laws. One controlled observational study found an association between residential smoke alarm legislation and a reduced likelihood of fire death, but the effectiveness and cost effectiveness of smoke alarm legislation in preventing fire deaths and injuries has yet to be adequately evaluated.

Smoke alarms are relatively inexpensive, but to install alarms in all inner city homes and to ensure compliance with any legislation would have important resource implications. If this had little or no effect on the prevention of fire deaths and injuries, then such a policy would incur an important opportunity cost. But is a scenario plausible where the costs of increasing smoke alarm ownership outweigh the benefits, given the evidence of benefit from ecological, case-control and non-randomised intervention studies? The answer must surely be yes. Results from ecological studies do not constitute reliable evidence of the effectiveness of smoke alarm interventions. Confounding by factors related to poverty might easily account for the strong association observed in case-control studies, because poverty is a strong risk factor for fire death and poor families are least likely to have smoke alarms. Similarly, the 80% reduction in serious fire related injuries seen during the four years after the Oklahoma City giveaway programme must also be considered with caution. It is well established that non-randomised studies can overestimate the effectiveness of interventions when compared with results from randomised controlled trials.

Neither giving away free smoke alarms nor enacting legislation requiring alarm installation in materially deprived areas will necessarily increase the prevalence of functioning alarms. A survey of inner London public housing found that only half of installed smoke alarms were functioning. In most cases of non-function, the installed alarms had no batteries. Tenants may remove batteries because of nuisance alarms during cooking and smoking. Such nuisance alarms may be particularly problematic among families living in bed-sit accommodation and in overcrowded conditions. However, failure to maintain a functioning smoke alarm does not signal a feckless disregard for safety. Although residential fires are a leading cause of death in childhood, for families living in the inner city slums there are many competing concerns. One inner London health authority asked residents about their concerns for health and safety in the context of an urban regeneration programme. Discarded syringes from heroin use and used condoms from prostitution were the main fears, and the residents called foremost for improved refuse collection. Given these concerns—and the daily privations of squalid inner city housing, such as broken windows, urine in the stairwells, lifts that do not work, racist graffiti, and violence—it is not hard to understand why smoke alarms are not top on the list of priorities. Clearly, without reliable evidence of effectiveness and cost effectiveness, smoke alarm giveaway programmes or legislation run the risk of diverting scarce resources from other important concerns that may have greater benefit to the population.

Randomised controlled trials are the gold standard for the evaluation of healthcare interventions. There is no good reason why interventions to prevent fire injury should not be evaluated in the same way. Smoke alarms are only one approach to the prevention of fire deaths and injuries, but a particularly promising one. Some countries and states mandate the use of smoke alarms, others do not. On the basis of the existing evidence it is easy to make an argument for smoke alarm legislation, but it is also an easy argument to refute. Reliable evidence from large scale randomised controlled trials of smoke alarm interventions could change this. The Salk vaccine trial reliably established the effectiveness of polio vaccine and laid the foundations for the current efforts to eradicate polio. Our aspirations for injury prevention should be no less.

Our responsibility to children and adolescents

A child falls from an open apartment window without a window guard and suffers a severe, disabling head injury. A teenager amputates his finger while operating machinery at work. A family of four small children are severely burned in a house fire because their rental tenement did not have a smoke detector. Interventions to insure their widespread use and protection have played a large part in the reduction of these injuries.

Injuries are caused by a complex interplay of agent, host, and environment. Environmental hazards such as open windows, unguarded machinery, or sleeping in a home without a smoke detector account for the vast majority of deaths due to injury over the last few decades.

We all have a responsibility to children and adolescents. These arguments are also not limited to the discussion of child injury prevention in the UK, but are relevant to the prevention of adult injuries in countries around the world.

Injuries are cased by a complex interplay of agent, host, and environment. Environmental hazards are especially important in the etiology of child and adolescent injury where the limited experience and judgment of children and adolescents cannot counter the effects of environmental hazards such as open windows, unguarded machinery, or sleeping in a home without a smoke detector. Interventions focused on environmental modification have been some of the most powerful tools in the injury prevention armamentarium. They have played a large part in the reduction of deaths due to injury over the last two decades.

These changes in the environment have not necessarily occurred easily, and have often required government intervention to insure their widespread use and protection.
of those most vulnerable in our society, namely poor children. Safety often costs money; the nature of business, on the other hand, is to maximize profits. New York City requires that windows in high rise housing be fitted with window guards to prevent falls. Labor regulations prevent teenagers under 16 from operating machinery in the workplace. In the US, nearly all jurisdictions require landlords to equip rental housing with functional smoke detectors. Few of us believe that motor vehicles would be as safe as they are today without government standards and regulation.

Children, especially poor children, are the group most vulnerable to injury. Societies have generally recognized that these individuals do not decide for themselves where they live, and thus the hazards to which they are exposed. If their parents are unwilling or unable to provide for a safe environment, it is the responsibility of the state to insure that children are safe from harm. This is true whether the environment is the workplace, or firetrap housing.

Physicians should and must look beyond individual health to the health of the public. Their responsibility for the health and welfare of patients, whether they be children or adults, does not end at the examining room door. Just as we send out public health officials to trace an infectious disease outbreak, we should send public health officials to trace the source and cause of high rates of injury in a specific group, whether that group be children and adolescents, the poor, or families on a specific street. Just as all politics is ultimately local, so too all injury prevention is ultimately finding a specific risk in a local community and changing it.

Putting a brake on carnage

Road deaths in England stopped falling in 1998 after seven years of steady decline. Recent figures showed that rear-end collisions are the most common and are caused by drivers failing to concentrate and anticipate. National Road Safety Week in July involved 200 organisations to ask motorists to think about their driving—to drive at appropriate speeds and to keep a safety space round the car. Accidents are a huge drain on the economy. Preventing one fatal day time accidents on a motorway in England would save more than £1 million. Even a crash causing only minor injuries costs the taxpayer £16 700 (Mail on Sunday (London), July 1999).

Holidays hurt

A British mother, who was an experienced horse rider, was killed in a riding accident while on holiday in Montana. She was dragged to her death when her foot slipped through a stirrup and her horse bolted. Her head was only protected by a cowboy hat, and she struck against a rock (Daily Mail (London), June 1999).

A Briton who died after being thrown from a horse while on holiday in Tunisia, might have survived had she been wearing a riding hat, an inquest was told. Her horse bolted and threw her off, leaving her on the ground with blood coming from her ear. She died five days later from head injuries. She and other riders had not been offered hard hats by the riding school before they set off (The Times (London), June 1999).

After five drowning accidents in a two week period in June/July, Spanish authorities have promised a full investigation into the safety of hotel swimming pools. The Federation of Tour Operators, which represents most of the UK’s travel companies, have been campaigning for better poolside safety for the past 10 years. In 1996, a Which? report into swimming pool safety in Turkey and Gran Canaria claimed that 12 of the 39 hotel pools surveyed were “dangerous” (Sunday Times (London), July 1999).

Garden dangers

A footballer was killed when he slipped on wet grass during a garden “kick-around” and crashed head first into a greenhouse. He had been playing soccer with children at a family barbeque and he bled to death after a shard of glass severed a main artery (Daily Mail (London), June 1999).

A missile thrown up by the blades of a ride-on lawnmower struck a young man on the head and fatally injured him. He was moving a swing, while his father moved the grass, when something hit him. A postmortem showed he suffered a depressed skull fracture and a piece of bone was lodged in his brain. The missile was never found (Irish Times (Dublin), June 1999).

A business man who disappeared while working in his garden died when he jumped into the river after accidentally setting fire to himself. He had used petrol to sprinkle on a bonfire which then set fire to his clothing. He jumped into the river to douse the flames but drowned.
